Grossmanite, CaTi\textsuperscript{3+}AlSiO\textsubscript{6}, a new pyroxene from the Allende meteorite

CHI MA* and GEORGE R. ROSSMAN

Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, California 91125, U.S.A.

ABSTRACT

Grossmanite, Ca(Ti\textsuperscript{3+},Mg,Ti\textsuperscript{4+})AlSiO\textsubscript{6} with an end-member formula CaTi\textsuperscript{3+}AlSiO\textsubscript{6} is a new member of the Ca clinopyroxene group, where the trivalent cations are dominant in the M1 site with Ti\textsuperscript{3+} being the dominant trivalent cation. It occurs as micrometer-sized crystals along with spinel and perovskite in a melilite host in Ca-Al-rich refractory inclusions from the Allende meteorite. The mean chemical composition determined by electron microprobe analysis of the type material is (wt%) SiO\textsubscript{2} 27.99, Al\textsubscript{2}O\textsubscript{3} 24.71, CaO 24.58, TiO\textsubscript{2} 10.91, TiO\textsubscript{3} 6.68, MgO 4.45, Sc\textsubscript{2}O\textsubscript{3} 0.43, V\textsubscript{2}O\textsubscript{3} 0.19, ZrO\textsubscript{2} 0.13, FeO 0.08, Cr\textsubscript{2}O\textsubscript{3} 0.03, sum 100.20. Its empirical formula calculated on the basis of 6 O atoms is Ca\textsubscript{1.00}(Ti\textsubscript{0.35}Al\textsubscript{0.25}Sc\textsubscript{0.01}V\textsubscript{0.01})\textsubscript{2}O\textsubscript{3}0.55Mg\textsubscript{0.23}Ti\textsubscript{0.19}Mn\textsubscript{0.01}(Si\textsubscript{1.0}Al\textsubscript{0.09})\textsubscript{2}O\textsubscript{6}. Grossmanite is monoclinic, C2/c; a = 9.80 Å, b = 8.85 Å, c = 5.36 Å, β = 105.62°, V = 447.70 Å\textsuperscript{3}, and Z = 4. Its electron back-scatter diffraction pattern is an excellent match to that of Ti\textsuperscript{3+}-rich pyroxene with the C2/c structure. The five strongest calculated X-ray powder diffraction lines are [d spacing in Å, (I), hkl] 2.996 (100) (211), 2.964 (31) (310), 2.581 (42) (002), 2.600 (28) (T31), 2.535 (47) (221). The name is for Lawrence Grossman, a cosmochemist at the University of Chicago.

Keywords: Grossmanite, Ca(Ti\textsuperscript{3+},Mg,Ti\textsuperscript{4+})AlSiO\textsubscript{6}, CaTi\textsuperscript{3+}AlSiO\textsubscript{6}, new mineral, Ti-rich pyroxene, refractory inclusion, Allende meteorite, carbonaceous chondrite

INTRODUCTION

During a nano-mineralogical investigation of the Allende meteorite (a CV3), Ti-rich pyroxenes were observed in Ca-AI-rich refractory inclusions (CAI). Electron-microprobe, high-resolution SEM, electron backscatter diffraction (EBSD), and Raman analyses have been used to characterize its composition and structure. Highly Ti-enriched clinopyroxenes (16–18 wt% total TiO\textsubscript{2}) have been observed in Allende since its fall in 1969 (e.g., Fuchs 1971; Dowty and Clark 1973; Mason 1974; Simon et al. 1999). We report here the occurrence, composition and crystal symmetry of a clinopyroxene from Allende, Ca(Ti\textsuperscript{3+},Mg,Ti\textsuperscript{4+})AlSiO\textsubscript{6}, where Ti\textsuperscript{3+} is the dominant trivalent component and the trivalent cations are dominant in the M1 site. The newly approved dominent-valency rule (Hatert and Burke 2008) is applied here to designate this pyroxene as a new mineral.

MINERAL NAME AND TYPE MATERIAL

The new mineral and its name have been approved by the Commission on New Minerals, Nomenclature and Classification (IMA 2008-042a). The name is for Lawrence Grossman, Professor of Cosmochemistry at the University of Chicago, born in 1946, in honor of his fundamental contributions to meteorite research. Type material (Caltech Section Allende12 MC21) has been deposited in the Smithsonian Institution’s National Museum of Natural History and is cataloged under USNM 7562.

OCCURRENCE, ASSOCIATED MINERALS, AND ORIGIN

Micrometer-sized grossmanite (the type material) occurs with MgAl\textsubscript{2}O\textsubscript{4} spinel and CaTiO\textsubscript{3} perovskite in a melilite [Ca\textsubscript{2.96}(Al\textsubscript{2.94}Mg\textsubscript{0.06})\textsubscript{2}(Si\textsubscript{1.06}Al\textsubscript{0.94})O\textsubscript{12}] host in a CAI fragment from the Allende meteorite (Fig. 1). The inclusion with a Wark-Lovering rim is exposed in one polished thick section, prepared from a 1 cm Allende specimen at Caltech. This CAI fragment is 330 × 385 μm in the section plane, surrounded by a matrix of mostly olivine and troilite. The Allende meteorite, which fell at Puebloito de Allende, Chihuahua, Mexico, on February 8, 1969, is a CV3 carbonaceous chondrite.

Grossmanite is also observed in a Type B1 CAI from Allende in sections USNM 7554 and USNM 7555 (which were previously Caltech sections), occurring with spinel, perovskite, grossite in melilite near the rim, as shown in Figure 2.

APPEARANCE, PHYSICAL AND OPTICAL PROPERTIES

The type material (1–7 μm in size) appears to coat spinel grains (Fig. 1). In thin section, it is transparent with a light-gray color that may be caused by adjacent and underlying phases. Streak, luster, hardness, tenacity, cleavage, fracture, and density were not determined because of the small grain size. The density, calculated from the empirical formula, is 3.41 g/cm\textsuperscript{3}. It is non-fluorescent under the beams of the electron microprobe and SEM. Optical properties were not determined because of the small grain size. In the section, the crystal grains are irregular. No crystal forms or twinning were observed. The a:b:c ratio calculated from the unit-cell parameters is 1.107:1.0:1.66. Larger crystals of grossmanite in USNM 3848 (Dowty and Clark 1973) and Ti-rich diopside in TS32 (Simon et al. 1999) show a green color under oblique illumination.

CHEMICAL COMPOSITION

Quantitative elemental microanalyses were conducted with the JEOL 8200 electron microprobe operated at 15 kV and 10 nA in a focused beam mode. Standards for the analysis were
was confirmed and cell constants were obtained by matching 1550VP scanning electron microscope, operated at 20 kV and 6 nA in a focused beam with a 70° tilted stage. The structure was confirmed and cell constants were obtained by matching the experimental EBSD pattern (Fig. 3) with the structures of Ti<sup>4+</sup> pyroxene (Dowty and Clark 1973), synthetic CaScAlSiO<sub>6</sub> (Ohashi and Ii 1978), esseneite (Cosca and Peacor 1987), and orthorhombic pyroxenes (Molin 1989).

The EBSD patterns can be indexed only by the monoclinic C2/c structure to give a best fit based on unit-cell data from Ti-rich pyroxene (Dowty and Clark 1973) (Fig. 3), showing a monoclinic structure, space group: C2/c, a = 9.80 Å, b = 8.85 Å, c = 5.36 Å, β = 105.62°, V = 447.70 Å<sup>3</sup>, and Z = 4 with the mean angular deviations as low as 0.26. No errors are stated because the cell parameters are taken directly from the data of the matching phase in Dowty and Clark (1973). The Ti-rich pyroxene in USNM 3848 characterized by Dowty and Clark (1973) is grossmanite with a formula Ca<sub>1.01</sub>([Ti<sup>4+</sup>]<sub>0.13</sub>Al<sub>0.91</sub>O<sub>2</sub>·6Mg<sub>0.03</sub>Sc<sub>0.01</sub>Ti<sup>4+</sup>]<sub>0.09</sub>Σ<sub>0.10</sub>Co<sub>0.01</sub>Σ<sub>0.10</sub>Mg<sub>0.29</sub>Si<sub>0.01</sub>O<sub>2</sub>Σ<sub>0.13</sub>0.02O<sub>0.04</sub>0.02O<sub>0.04</sub>. X-ray powder-diffraction data (CuKα) are calculated from the cell parameters from Dowty and Clark (1973) with the empirical formula of the type grossmanite from this study (Table 1) using Powder Cell version 2.4 (2000). The strongest X-ray powder diffraction lines are [d spacing in Å, (hkl), 2θ] 2.996 (100) (221), 2.964 (31) (310), 2.909 (25) (231), 2.581 (42) (002), 2.600 (28) (231), 2.535 (47) (221), 2.130 (19) (211), 1.650 (18) (223), 1.431 (19) (531).

**Spectroscopic properties**

Raman microanalysis was carried out using the methods described in Ma and Rossman (2008, 2009a). Raman analysis gave

*Total titanium, which equals 18.80 wt% as TiO<sub>2</sub>, has been partitioned between Ti<sup>4+</sup> and Ti<sup>4+</sup> to make ideal stoichiometry.
no indication of either H₂O or CO₂ in grossmanite. Raman microanalyses show that the spectra of grossmanite (using a 514.5 nm laser) in USNM 7555 are close to those of Ti-rich diopside in TS32 and esseneite (RRUFF -R061123) (see supplemental figure1 on deposit), whereas the spectrum of the type grossmanite in USNM 7562 shows numerous fluorescence features in the 1500 to 900 cm⁻¹ and some in the 900–200 cm⁻¹ region due either to likely traces of REE in the structure or coming from signal spillover from adjacent phases such as perovskite.

Optical absorption spectra (Fig. 4) indicate that grossmanite and Ti-rich diopside from Allende contain a significant amount of Ti³⁺ in the structure that causes the green color. The dominant absorption features are a rising absorption toward shorter wavelength with two superimposed absorption bands at 490 and 608 nm. Previous studies of a pyroxene from the Allende meteorite (Dowty and Clark 1973) have demonstrated that Ti³⁺ in the pyroxene’s M1 site produces optical absorption bands centered at nearly the same wavelengths (490 and 606 nm) in a sample with much lower Ti content. Other synthetic Ti³⁺-containing pyroxenes of somewhat different composition have been studied and were found to have a pair of bands at somewhat longer wavelengths than the Allende pyroxenes. Skogby et al. (2006) examined the optical absorption spectrum of a series of synthetic, Ti-doped diopside samples and found two bands centered at 547 and 637 nm that correlated with the amount of Ti³⁺. In addition, an optical absorption spectrum of a sample of synthetic NaTi³⁺Si₆O₈ (GRR216) synthesized by RD Shannon (Prewitt et al. 1972) was obtained (Fig. 4). It also had a pair of absorption bands (540 and 625 nm) intermediate between those of the diopsidic titanian pyroxene of Skogby et al. (2006) and grossmanite samples, and essentially identical to the spectrum of the same compound reported by Skogby et al. (2006) where they report bands at 547 and 637 nm.

Ti³⁺, by itself, has an empty d-orbital electronic configuration and is incapable of causing optical absorption in the visible range. Fe²⁺-Ti³⁺ intervalence charge transfer produces only a single band at lower wavelengths in pyroxenes (Mao et al. 1977).

A crude estimate of the amount of Ti³⁺ in grossmanite can be established using the intensity of the Ti³⁺ absorption in the NaTi³⁺Si₆O₈ spectrum reported by Skogby et al. (2006) who observed a Ti³⁺ band intensity of about 120 per cm at 15 700 cm⁻¹ for the M1 site completely occupied by Ti³⁺. The corresponding band in the grossmanite spectrum has an intensity of about 12 per cm corresponding to minimum of about 0.18 of a site occupied by Ti³⁺. This estimate is a minimum because the grossmanite crystal was not oriented in a direction to obtain an optimal polarization direction. Nevertheless, this estimate compares favorably with the 0.348 apfu from the empirical formula determined from the electron-probe analysis. While the exact intensity of Ti³⁺ absorption in grossmanite is unknown, this estimate demonstrates a substantial amount of Ti³⁺ in this phase.

**DISCUSSION**

Grossmanite is a new member of the Ca clinopyroxenes (diopside group) with space group C2/c, the Ti³⁺-dominant analog of esseneite (CaFe²⁺AlSiO₆) (Cosca and Peacor 1987), davisite (CaScAlSiO₆) (Ma and Rossman 2009b), kushiroite (CaTi pyroxene, CaAlAlSiO₆) (Kimura et al. 2009; Ma et al. 2009), where the trivalent cations are dominant in the M1 site with Al occupying about 50% of the tetrahedral Si site. As shown in Figure 5, there seems to be a solid solution among diopside,

**FIGURE 4.** Optical absorption spectra of a 52 μm thick Ti-rich diopside in TS32 (this study), grossmanite in USNM3848 of unspecified thickness (Dowty and Clark 1973), and a 30 μm thick synthetic NaTi²⁺Si₆O₈ pyroxene (GRR216). The Ti-rich diopside and grossmanite are polarized in two extinction directions in the section plane. Each pair of spectra has been displaced vertically for clarity.
term “fassaite” refers to Ti-bearing and Al-rich Ca clinopyroxene in refractory inclusions from chondrites (Dowty and Clark 1973; Brearley and Jones 1998), which is well known and widely used in the meteoritics community, although the name was discredited officially by the IMA-CNMC (Morimoto et al. 1988). By definition, Ti-rich “fassaite” pyroxenes are grisefissalite if trivalent cations dominate the M1 site from Allende clinopyroxenes of this study, Ma and Grossman (2009b) and Ma et al. (2009); (b) normalized ternary diagram of Ti\(^{3+}\)-Se\(^{2+}\)-Al\(^{3+}\) from the same clinopyroxenes where the trivalent cations are dominant in the M1 site. Square = grossmanite (USNM 7562, 7555, 7554); circle = davisite (USNM 7555); triangle = kushiroite (USNM 7554; ALH1); diamond = Ti-rich diopside (USNM 7554, TS32).

grossmanite, davisite, and kushiroite based on this study and on Ma and Grossman (2009b) and Ma et al. (2009).

Term “fassaite” refers to Ti-bearing and Al-rich Ca clinopyroxene in refractory inclusions from chondrites (Dowty and Clark 1973; Brearley and Jones 1998), which is well known and widely used in the meteoritics community, although the name was discredited officially by the IMA-CNMC (Morimoto et al. 1988). By definition, Ti-rich “fassaite” pyroxenes are grisefissalite if trivalent cations dominate the M1 site with Ti\(^{3+}\) being the dominant trivalent cation (Fig. 5). If trivalent cations dominate the M1 site with Se\(^{2+}\) the dominant trivalent cation, such “fassaite” is davisite. When trivalent cations dominate the M1 site with Al the dominant trivalent cation, the “fassaite” is kushiroite. If Mg\(^{2+}\) is dominant in the M1 site, the “fassaite” is diopside.

The Allende meteorite containing 0.15 wt% total TiO\(_2\) (Jaroszewich et al. 1987) has provided a variety of phases with high titanium contents including oxides, pyroxenes, perovskite, and zirconolite as primitive refractory phases. Grossmanite and Ti-rich diopside often have Ti in both 3+ and 4+ oxidation states. Such pyroxenes formed in a reducing environment (Beckett 1986). Another newly discovered mineral tistarite (Ti\(_3\)O\(_6\), IMA 2007-027) from Allende is the most Ti\(^{3+}\)-rich mineral in nature (Ma and Rossman 2009a). Refractory phases are the first known solids formed in the solar system. Grossmanite is a refractory mineral from Allende, associated with Mg-Al spinel, perovskite, and melilite in CAIs, which are likely formed through high-temperature condensation in the solar nebula, followed by melting and crystallization. Grossmanite apparently formed after the appearance of spinel and perovskite but before crystallization of melilitc in the type material setting.

Acknowledgments

The Caltech Analytical Facility at the Division of Geological and Planetary Sciences is supported, in part, by grant NSF EAR-0318518 and the MRSEC Program of the NSF under DMR-0080065. Funding from NSF grant EAR-0337816 is also acknowledged. Discussions with L. Grossman and J.R. Beckett on meteoritic “fassaite” pyroxenes are gratefully acknowledged. We thank S.B. Simon for providing section TS32 and R.D. Shannon for providing the synthetic NaTi\(_3\)SiO\(_4\) crystals. We thank H. Skogby and A. Rubin for constructive reviews of this manuscript and P. Williams for helpful suggestions regarding the new mineral proposal.
